#### Abstract

Artificial Bee Colony (ABC) algorithm has been emerged as one of the latest Swarm Intelligence based algorithm. Though, ABC is a competitive algorithm as compared to many other optimization techniques, the drawbacks like preference on exploration at the cost of exploitation and skipping the true solution due to large step sizes, are also associated with it. In this paper, two modifications are proposed in the basic version of ABC to deal with these drawbacks: solution update strategy is modified by incorporating the role of fitness of the solutions and a local search based on greedy logarithmic decreasing step size is applied. The modified ABC is named as accelerating ABC with an adaptive local search (AABCLS). The former change is incorporated to guide to not so good solutions about the directions for position update, while the latter modification concentrates only on exploitation of the available information of the search space. To validate the performance of the proposed algorithm AABCLS, 30 benchmark optimization problems of different complexities are considered and results comparison section shows the clear superiority of the proposed modification over the Basic ABC and the other recent variants namely, Best-So-Far ABC

[^0](BSFABC), Gbest guided ABC (GABC), Opposition based levy flight ABC (OBLFABC) and Modified ABC (MABC).

Keywords Artificial Bee Colony • Memetic algorithm • Optimization • Exploration-exploitation • Swarm Intelligence

## 1 Introduction

Swarm Intelligence is one of the recent outcome of the research in the field of Nature inspired algorithms. The collaboration among social insects while searching for food and creation of the intelligent structures is known as Swarm Intelligence. Ant colony optimization (ACO) [12], particle swarm optimization (PSO) [27], bacterial foraging optimization (BFO) [39] are some examples of swarm intelligence based optimization techniques. The work presented in the articles [12,27,40,53] proved its efficiency and potential to deal with non-linear, non convex and discrete optimization problems. Karaboga [24] contributed the recent addition to this category, known as Artificial Bee Colony (ABC) optimization algorithm. The $A B C$ algorithm mimics the foraging behavior of honey bees while they search for food. ABC is a simple and population based optimization algorithm. Here the population consists of possible solutions in terms of food sources for honey bees. A food source's fitness is measured in terms of nectar amount which the food source contains. The swarm updating in ABC is due to two processes namely, the variation process and the selection process which are responsible for exploration and exploitation, respectively. It is observed that the position update equation of ABC algorithm is good at exploration but poor at exploitation [56] i.e, ABC has not a proper balance between exploration and exploitation. Therefore these drawbacks require a modification in position
update equation and/or a local search approach to be implemented in ABC. These drawbacks have also been addressed in earlier research. To enhance the exploitation, Gao and Liu [16] improved position update equation of $A B C$ such that the bee searches only in neighborhood of the previous iteration's best solution. Banharnsakun et al. [3] proposed the best-so-far selection in ABC algorithm and incorporated three major changes: The best-so-far method, an adjustable search radius, and an objective-value-based comparison in ABC. To solve constrained optimization problems, Karaboga and Akay [26] used Deb's rules consisting of three simple heuristic rules and a probabilistic selection scheme in ABC algorithm. Karaboga [24] examined and suggested that the limit should be taken as $S N \times D$, where, $S N$ is the population size and $D$ is the dimension of the problem and coefficient $\phi_{i j}$ in position update equation should be adopted in the range of $[-1,1]$. Further, Kang et al. [22] introduced exploitation phase in ABC using Rosenbrock's rotational direction method and named modified ABC as Rosenbrock ABC (RABC).

In this paper two modifications in ABC are proposed. First, position update equation of basic ABC is modified based on the fitness such that the solutions having relatively low fitness search near the global best solution of the current swarm only and other solutions having better fitness include information of the global best solution and a random solution in their position update procedure. Second and an effective modification is the incorporation of a local search strategy in ABC based on greedy and logarithm decreasing range of step size. This local search strategy is inspired from logarithmic decreasing inertia weight strategy proposed in [17]. Our proposed modified ABC variant is named as Accelerating ABC with an adaptive local search (AABCLS).

The rest of the paper is organized as follows: Sect. 2 summarizes different local search strategies which have been incorporated in various optimization algorithms. ABC algorithm is explained in Sect. 3. Section 4 presents the modified ABC called AABCLS algorithm. The experimental results and discussions are presented in Sect. 5. Finally, the conclusion is drawn in Sect. 6.

## 2 Brief review on local search strategies

In the field of optimization, local search strategy is an interesting and efficient help for population based optimization methods while solving complex problems [37]. The population based optimization algorithm hybridized with local improvement strategy is termed as Memetic Algorithm (MA), initially by Moscato [32]. The traditional examples of population-based methods are Genetic Algorithms, Genetic Programming and other Evolutionary

Algorithms, on the other hand Tabu Search and Simulated Annealing are two prominent local search representatives. The global search is expected to detect the global optimum while the obvious role of local search algorithm must be to converge to the closest local optimum. Local search strategies can be stochastic/deterministic, single/multi agent based, steepest descent/greedy approach based procedures [34]. Therefore, in order to maintain the proper balance between exploration and exploitation in an algorithmic process, a local search strategy is highly required to be incorporated within the basic population based algorithm.

Nowadays, researchers are continuously working to enhance the exploitation capability of the population based algorithms by hybridizing the various local search strategies within these [4,8,21,31,33,38,45,47,54]. Further, Memetic Algorithms are also applied to solve complex optimization problems like continuous optimization [36,38], flow shop scheduling [21], machine learning [7,20,44], multiobjective optimization $[18,28,50]$, combinatorial optimization [21,42,51], bioinformatics [15,43], scheduling and routing [6], etc.

In the past, few more efforts have been made to incorporate a local search within ABC. Thammano and Phu-ang [52] proposed a hybrid ABC algorithm for solving the flexible job shop scheduling problem in which they incorporated five different local search strategies at different phases of the ABC algorithm to accomplish different purposes. To initialize the individual solution, the harmony search algorithm is considered. To search another solution in the neighborhood of a particular solution, the iterated local search technique, the scatter search technique, and the filter and fan algorithm are used. Finally, the simulated annealing algorithm is employed on a solution which is trapped in a local optimum. Sharma et al. [46] incorporated a power law-based local search strategy with DE. Fister et al. [14] developed a memetic ABC (MABC) which is hybridized with two local search heuristics: the Nelder-Mead algorithm ( $N M A$ ) for exploration purpose and the random walk with direction exploitation $(R W D E)$ for exploitation purpose. Here stochastic adaptive rule as specified by Neri [9] is applied for balancing the exploration and exploitation. Tarun et al. [48] developed an algorithm called improved local search in ABC using golden section search where golden section method is employed in onlooker phase. Ong and Keane [36] proposed various local search techniques during a Memetic Algorithm search in the sprit of Lamarckian learning. Further they also introduced different strategies for MAs control which choose one local search amongst the others at runtime for the exploitation of the existing solution. Nguyen et al. [35] presented a different probabilistic memetic framework that models MAs as a process involving the decision of embracing the separate actions of evolution
or individual learning and analyzed the probability of each process in locating the global optimum. Further, the framework balances evolution and individual learning by governing the learning intensity of each individual according to the theoretical upper bound derived while the search progresses.

A Hooke and Jeeves method [19] based local search is incorporated in basic ABC algorithm by Kang et al. [23] which is known as (HJABC) for numerical optimization. In the HJABC, the calculation of fitness function $\left(f i t_{i}\right)$ of basic $A B C$ is also changed as in Eq. (1).
$f i t_{i}=2-S P+\frac{2(S P-1)\left(p_{i}-1\right)}{N P-1}$,
here $N P$ is the total number of solutions, $p_{i}$ is the position of the solution in the whole population after ranking, $S P \in[1.0,2.0]$ is the selection pressure. Further, MezuraMontes and Velez-Koeppel [30] introduced a Elitist ABC with two different local search strategies and which one out of both strategies will work at a time, is regulated through the count on function evaluations. Here, best solution in the current swarm is improved by generating a set of 1000 new food sources in its neighborhood. Kang et al. [22] proposed a Rosenbrock ABC (RABC) where exploitation phase is introduced in the ABC using Rosenbrock's rotational direction method.

## 3 Artificial Bee Colony (ABC) algorithm

The ABC algorithm is a population based Swarm Intelligence algorithm which is inspired by food foraging behavior of honey bees. In ABC, each solution is known as food source of honey bees whose fitness is determined in terms of the quality of the food source. Artificial Bee Colony is made of three groups of some bees: employed bees, onlooker bees and scout bees. The number of employed and onlooker bees is equal. The employed bees search the food source in the environment and store the information like the quality and the distance of the food source from the hive. Onlooker bees wait in the hive for employed bees and after collecting information from them, they start searching in neighborhood of those food sources which have better nectar. If any food source is abandoned then scout bee finds new food source randomly in the search space. While searching the solution of any optimization problem, ABC algorithm first initializes $A B C$ parameters and swarm then it requires the repetitive iterations of the three phases, namely employed bee phase, onlooker bee phase and scout bee phase. The pseudo-code of the ABC algorithm is shown in Algorithm 1 [25]. Working procedure of each phase for ABC algorithm is explained in the Sects. 3.1-3.4.

```
Algorithm 1 Artificial Bee Colony Algorithm
    Initialize the parameters and swarm members;
    while Termination criteria not satisfied do
        Step 1: Employed bee phase for generating new food sources using
        Equation 3;
        Step 2: Onlooker bees phase for updating the food sources using
        Equation 3 depending on their probabilities described in Equation
        4;
        Step 3: Scout bee phase for discovering the new food sources using
        Equation 2 in place of abandoned food sources;
        Step 4: Memorize the best food source found so far;
    end while
    Output the best solution found so far.
```

### 3.1 Initialization of the Swarm

The first step in $A B C$ is to initialize the solutions (food sources). If $D$ is the number of variables in the optimization problem then each food source $x_{i}(i=1,2, \ldots, S N)$ is a $D$-dimensional vector among the $S N$ food sources and is generated using a uniform distribution as:
$x_{i j}=x_{\operatorname{minj}}+\operatorname{rand}[0,1]\left(x_{\operatorname{maxj}}-x_{\operatorname{minj}}\right)$
here $x_{i}$ represents the $i$ th food source in the swarm, $x_{\text {minj }}$ and $x_{\operatorname{maxj}}$ are bounds of $x_{i}$ in $j$ th dimension and $\operatorname{rand}[0,1]$ is a uniformly distributed random number in the range $[0,1]$. After initialization phase ABC requires the cycle of the three phases, namely employed bee phase, onlooker bee phase and scout bee phase to be executed.

### 3.2 Employed bee phase

In this phase, $i$ th food source's position is updated using following Equation:
$v_{i j}=x_{i j}+\phi_{i j}\left(x_{i j}-x_{k j}\right)$
here $k \in\{1,2, \ldots, S N\}$ and $j \in\{1,2, \ldots, D\}$ are randomly chosen indices and $k \neq i . \phi_{i j}$ is a random number in the range $[-1,1]$. After generating new position $v_{i}$, the position with better fitness between the newly generated $v_{i}$ and the original $x_{i}$, is selected.

### 3.3 Onlooker bees phase

In this phase, employed bees share the information associated with its food source like quality (nectar) and position of the food source with the onlooker bees in the hive. Onlooker bees evaluate the available information about the food source and based on the food source's fitness, the onlooker bees select a food source with a probability $\operatorname{prob}_{i}$. Here $\mathrm{prob}_{i}$ can be calculated as function of fitness (there may be some other):
$\operatorname{prob}_{i}(G)=\frac{0.9 \times \text { fitness }_{i}}{\text { maxfit }}+0.1$,
here fitness $s_{i}$ is the fitness value of the $i$ th solution (food source) and maxfit is the maximum fitness amongst all the food sources. Based on this probability, onlooker selects a food source and modifies it using the same Eq. (3) as in employed bee phase. Again by applying greedy selection, if the fitness is higher than the previous one, the onlooker bee stores the new food source in its memory and forgets the old one.

### 3.4 Scout bees phase

If a bee's food source is not updated for a fixed number of iterations, then that food source is considered to be abandoned and the corresponding bee becomes a scout bee. In this phase, the abandoned food source is replaced by a randomly chosen food source within the search space using the Eq. (2) as in initialization phase. In ABC , the number of iterations after which a particular food source becomes abandoned is known as limit and is a crucial control parameter.

## 4 Accelerating Artificial Bee Colony algorithm with an adaptive local search

In this section, the proposed Accelerating ABC Algorithm with an adaptive local search (AABCLS) is introduced in detail. To be specific, in order to better guide the bees during the searching process, the existing ABC frame-work is modified. Here two modifications in ABC are proposed: first, the position update equation for solutions is modified and second, a new self adaptive local search strategy is incorporated with ABC. An algorithm which establishes a proper balance between exploration and exploitation capabilities, is considered as an efficient algorithm. In other words, an algorithm is regarded as reliable and widely applicable if it can balance exploration and exploitation during the search process. ABC algorithm achieves a good solution at a significantly faster rate, but it is weak in refining the already explored search space. Moreover, basic ABC itself has some drawbacks, like stop proceeding toward the global optimum even though the population has not converged to a local optimum [25]. These drawbacks make ABC a candidate to modify so that it can search solution more efficiently. The motivation for the proposed modifications in ABC can be described as follows:

1. Why modification is required in position update equation? In ABC, at any instance, a solution is updated through information flow from other solutions of the swarm. This position updating process uses a linear combination of current position of the potential solution which
is going to be updated and position of a randomly selected solution as step size with a random coefficient $\phi_{i j} \in[-$ $1,1]$. This process plays an important role to decide the quality of the new solution. If the current solution is far from randomly selected solution and absolute value of $\phi_{i j}$ is also high then the change will be large enough to jump the true optima. On the other hand, small change will decrease the convergence rate of the whole ABC process. Further, It is also suggested in literatures [25,56] that basic ABC itself has some drawbacks, like stop proceeding toward the global optimum even though the population has not converged to a local optimum and it is observed that the position update equation of ABC algorithm is good at exploration but poor at exploitation. Karaboga and Akay [25] also analyzed the various variants of $A B C$ and found that the ABC shows poor performance and remains inefficient to balance the exploration and exploitation capabilities of the search space. Therefore, the amount of change in the solution (say, step size) should be taken care of to balance the exploration and exploitation capabilities of the ABC algorithm. But this balance can not be done manually, as it consists of random coefficient $\phi_{i j}$.
2. Why an adaptive local search is incorporated with ABC? As mentioned earlier, if $\phi_{i j}$ and difference between randomly selected solution and current solution is high in position update equation of ABC then there will be sufficient chance that modified solution jump the global optima. In this situation, some local search strategy can help the search procedure. During the iterations, local search algorithm illustrates very strong exploitation capability [54]. Therefore, the exploitation capability of ABC algorithm may be enhanced by incorporating a local search strategy with ABC algorithm. In this way, the exploration and exploitation capability of ABC algorithm could be balanced as the global search capability of the ABC algorithm explores the search space or tries to identify the most promising search space regions, while the local search strategy will exploit the identified search space.

Hence, in this paper, the basic ABC is modified in two ways:

- In the position update equation of basic ABC (refer Eq. 3), individual candidate modifies its position by moving towards (or away from) a randomly selected solution. This randomly selected solution has equal chance to be good or bad, so there is no guaranty that new candidate position will be better than the last one. This scheme improves the exploration at the cost of exploitation. Hence, the solutions should not be allowed to follow blindly a randomly selected solution. Instead of this, it
may be a better strategy to compel less fit solutions to follow the best ever found solution through which the exploitation capability of ABC may be improved. Further, comparatively high fit solutions may be encouraged to use the information from best as well as a randomly selected individual to avoid premature convergence and stagnation. In this way, the higher fit solutions will be updated through a weighted sum of best and randomly selected solution and hence will not converge too quickly. In this strategy, to classify less and higher fit solutions, a probability $\operatorname{prob}_{i}$ (refer Eq. 4), which is a function of fitness, is applied.
In the proposed modification, if the value of prob $_{i}$ is $<0.5$ then the $i$ th solution is considered less fit solution than the other solutions in the swarm. So instead of searching around a randomly selected solution, this class of solutions (solutions for which prob $_{i}<0.5$ ) moves towards the best solution found so far in the swarm. For these solutions, the random solution $x_{k}$ in the position update equation of basic ABC is replaced by the best solution $\left(x_{\text {best }}\right)$ found so far and assigned a positive weight $\psi_{i j}$ to it in the interval $(0, C)$ as explained in Eq. (5), where $C$ is a positive constant. For detailed description of $C$ refer to [56]. On the other hand, relatively fit solutions (solutions for which $p r o b_{i} \geq 0.5$ ) are not allowed to blindly follow the direction of best solution in the swarm as it may be a local optimum and solutions may prematurely converge to it. Therefore, the position update equation of these solutions also includes the learning component of the basic ABC . The proposed position update equation is explained as below:
$v_{i j}=\left\{\begin{array}{cc}x_{i j}+\psi_{i j}\left(x_{\text {best }}-x_{i j}\right), & \text { if } \text { prob }_{i}<0.5 . \\ x_{i j}+\phi_{i j}\left(x_{i j}-x_{k j}\right) \\ & +\psi_{i j}\left(x_{\text {best }}-x_{i j}\right), \\ & \text { otherwise. }\end{array}\right.$
- In the second modification, a self adaptive local search strategy is proposed and incorporated with the ABC. The proposed local search strategy is inspired from logarithmic decreasing inertia weight scheme [17]. In the proposed local search strategy, the required step size (i.e., $\phi\left(x_{\text {current }}-x_{\text {random }}\right)$ ) to update an individual is reduced self adaptively to exploit the search area in the proximity of the best solution. Thus, the proposed strategy is named as self adaptive local search (SALS). In SALS, the step size is reduced as a logarithmic function of iteration counter as shown in Eqs. (7) and (8). In SALS, the random component ( $\phi_{i j}$ ) of basic ABC algorithm is optimized to direct the best solution to update its position. This process can be seen as an optimization problem solver which minimizes the unimodal continuous objective function $f\left(\phi_{i j}\right)$ in the direction provided
by the best solution $x_{\text {best }}$ over the variables $w_{1}, w_{2}$ in the interval $[-1,1]$ or simply it optimizes the following mathematical optimization problem:
$\min f(\phi)$ in $[-1,1]$;

SALS process starts with initial range ( $w_{1}=-1, w_{2}=$ 1) and generates two points in this interval by diminishing the edges of the range through a greedy way using the Eqs. (7) and (8). At a time, either of these Equations is executed depends which $f\left(w_{1}\right)$ or $f\left(w_{2}\right)$ has better fitness. If $w_{1}$ provides better fitness then edge $w_{2}$ of the range shrinks towards $w_{1}$ otherwise $w_{1}$ shifts itself near to $w_{2}$. The detailed implementation of SALS can be seen in Algorithm 2.

$$
\begin{align*}
& w_{1}=w_{1}+\left(w_{2}-w_{1}\right) \times \log (1+t / \text { maxiter })  \tag{7}\\
& w_{2}=w_{2}-\left(w_{2}-w_{1}\right) \times \log (1+t / \text { maxiter }) \tag{8}
\end{align*}
$$

where $t$ and maxiter are the current iteration counter and maximum allowable iterations in the local search algorithm respectively.

```
Algorithm 2 Self Adaptive Local Search (SALS) Strategy:
    Input: optimization function \(\operatorname{Minf}(x)\), the best solution \(x_{\text {best }}\);
    Initialize termination parameters \(\epsilon\), maximum number of iteration
    counter maxiter and variables \(w_{1}=-1, w_{2}=1\) and itercount \(=1\);
    while \(\left(\left|w_{1}-w_{2}\right|>\epsilon\right.\) and itercount \(\leq\) maxiter \()\) do
        Generate two new solutions \(x_{\text {new } 1}\) and \(x_{\text {new } 2}\) from \(x_{\text {best }}\) by using
        \(w_{1}\) and \(w_{2}\), respectively using Algorithm 3;
        Calculate \(f\left(x_{\text {new } 1}\right)\) and \(f\left(x_{\text {new } 2}\right)\);
        if \(f\left(x_{\text {new } 1}\right)<f\left(x_{\text {new } 2}\right)\) then
            \(w_{2}=w_{2}-\left(w_{2}-w_{1}\right) \times \log (1+\) itercount \(/\) maxiter \() ;\)
            if \(f\left(x_{\text {new }}\right)<f\left(x_{\text {best }}\right)\) then
            \(x_{\text {best }}=x_{\text {new } 1}\);
        end if
        else
            \(w_{1}=w_{1}+\left(w_{2}-w_{1}\right) \times \log (1+\) itercount \(/\) maxiter \() ;\)
            if \(f\left(x_{\text {new } 2}\right)<f\left(x_{\text {best }}\right)\) then
            \(x_{\text {best }}=x_{\text {new } 2}\);
        end if
        end if
        Set itercount \(=\) itercount +1 ;
    end while
```

Algorithm 2 terminates when either iteration counter exceeds the maximum iterations allowable in local search or absolute difference between $w_{1}$ and $w_{2}$ falls below a user defined parameter $\epsilon$. In Algorithm 3, $D$ is the dimension of the problem, $U(0,1)$ is a uniformly distributed random number in the range $(0,1), p_{r}$ is a perturbation rate and is used to control the amount of disturbance in the best solution $x_{\text {best }}$ and $x_{k}$ is a randomly selected solution from the population. For details, see the parameter settings in Sect. 5.1.

```
Algorithm 3 New solution generation:
    Input: \(w\) and best solution \(x_{\text {best }}\);
    for \(j=1\) to \(D\) do
        if \(U(0,1)<p_{r}\) then
            \(x_{\text {new } j}=x_{\text {best } j}+w\left(x_{\text {best } j}-x_{k j}\right) ;\)
        else
            \(x_{\text {new } j}=x_{\text {best } j} ;\)
        end if
    end for
    Return \(x_{\text {new }}\)
```

Fig. 1 Changes in the range $\left[w_{1}, w_{2}\right.$ ] during SALS in two dimension search space for $f_{26}$, refer Table 1

As the modifications are proposed to improve the convergence speed of ABC , while maintaining the diversity in the swarm. Therefore, the proposed strategy is named as "Accelerating ABC with an adaptive Local Search" (AABCLS).

It is clear from Algorithm 2 that only the best individual of the current swarm updates itself in its neighborhood. Further analyses of the proposed local search may be done through Figs. 1, 2 and 3. Figure 1 presents the variation of the range [ $w_{1}, w_{2}$ ] during the local search process. It is clear from this figure that the given range is iteratively reducing based on the movement of the best individual. Figure 2 shows the variations in the step size of the best individual during the local search. Figure 3 shows the movement of best individual during the local search in two dimension search space for Goldstein-Price function ( $f_{26}$ ), (refer Table 1).

The AABCLS is composed of four phases: employed bee phase, onlooker bee phase, scout bee phase and self adaptive local search phase. The scout bee phase is same as it was in basic ABC. The employed bee phase and onlooker bee phase are also same as in basic ABC except the position update equation. The position update equations of these phases have been replaced with the proposed position update Eq. (5). The last phase, namely self adaptive local search phase is executed after the completion of scout bee phase. The pseudo-code of the proposed AABCLS algorithm is shown in Algorithm 4.

Fig. 2 Variation in step size of best individual during SALS in two dimension search space for $f_{26}$, refer Table 1

Fig. 3 Best solution movement during SALS in two dimension search space for $f_{26}$, refer Table 1

```
\(\overline{\text { Algorithm } 4 \text { Accelerating ABC using adaptive local search }}\)
(AABCLS):
    Initialize the population and control parameters;
    while Termination criteria is not satisfied do
        Step 1: Employed bee phase to generate new food sources for each
        bee using proposed position update equation (5).
        Step 2: Onlooker bees phase to update the food sources using Equa-
        tion (5) based on their profitability.
        Step 3: Scout bee phase to determine the new food sources for
        exhausted food sources.
        Step 4: Apply self adaptive local search strategy phase to exploit
        the best solution found so far using Algorithm 2
    end while
    Return the best solution.
```

## 5 Experimental results and discussion

In this section, 30 benchmark functions which are used to investigate the algorithms' searching performance are described. The set of all the benchmark functions used, includes uni-model, multi-model, separable and non separable problems. Next, the detail of the simulation settings for all involved ABC's recent popular variants Best-So-Far ABC
(BSFABC) [3], Gbest-guided ABC (GABC) [56], Opposition Based Lévy Flight ABC (OBLFABC) [45] and Modified ABC (MABC) [1] are provided. Finally, the experimental results after analyzing and comparing the performance of the proposed algorithm AABCLS with ABC algorithm and its recent variants through distinct statistical tests are presented.

Table 1 includes 30 mathematical optimization problems ( $f_{1}$ to $f_{30}$ ) of different characteristics and complexities. These all problems are continuous in nature. Test problems $f_{1}-f_{21}$ and $f_{26}-f_{30}$ have been taken from [2] and test problems $f_{22}-f_{25}$ have been taken from [49] with the associated offset values. Authors decided to use this set of problems because it is versatile enough in nature which includes almost all type of problems like unimodelmultimodel, separable-nonseparable, scalable-non scalable and biased-unbiased optimization problems and if any algorithm can solve these problems of different characteristics then that algorithm may be considered as an efficient algorithm.

### 5.1 Experimental setting

The results obtained from the proposed AABCLS are stored in the form of success rate (SR), average number of function evaluations (AFE), standard deviation (SD) of the fitness and mean error (ME). Here $S R$ represents the number of times, algorithm achieved the function optima with acceptable error

- The terminating criteria: Either acceptable error (Table 1) meets or maximum number of function evaluations (which is set to be 200000) is reached,
- The proposed local search in ABC runs either 10 times (based on empirical experiment) for each iteration or $\mid w_{1}-$ $w_{2} \mid \leq \epsilon$ (here $\epsilon$ is set to 0.001 ) whichever comes earlier in algorithm.
- The parameter $p_{r}$ in Algorithm 3 is set to 0.4 based on its sensitive analysis in range $[0.1,1]$ as explained in the Fig. 4. Figure 4 shows a graph between $p_{r}$ and the sum of the successful runs for all the considered problems. It is clear that $p_{r}=0.4$ provides the highest success rate.
- Parameter settings for the other considered algorithms $\mathrm{ABC}, \mathrm{GABC}, \mathrm{BSFABC}, \mathrm{OBLFABC}$ and MABC are adopted from their original articles.

### 5.2 Results analysis of experiments

Table 2 presents the numerical results for benchmark problems of Table 1 with the experimental settings shown in Sect. 5.1. Table 2 shows the results of the proposed and other considered algorithms in terms of ME, SD, AFE and SR. Here $S R$ represents the number of times, algorithm achieved the function optima with acceptable error in 100 runs and $A F E$ is the average number of function evaluations called in 100 runs by the algorithm to reach at the termination criteria. Mathematically $A F E$ is defined as:

$$
A F E=\frac{\sum_{i=1}^{100} \text { Number of function evaluations to meet the termination criteria for run } i}{100}
$$

in 100 runs i.e, if an algorithm is applied 100 times to solve a problem then SR of the algorithm is the number of times it finds the optimum solution or a solution with acceptable error defined in Table 1 for that problem and $A F E$ is the average number of function evaluations called in 100 runs by the algorithm to reach at the termination criteria. Results for these test problems (Table 1) are also obtained from the basic ABC and its recent variants of ABC namely, BSFABC , GABC, OBLFABC and MABC for the comparison purpose. The following parameter setting is adopted while implementing our proposed and other considered algorithms to solve the problems:

- The number of simulations/run $=100$,
- Colony size $N P=50[11,13]$ and Number of food sources $S N=N P / 2$,
- All random numbers are generated using uniform probability distribution,
$-\phi_{i j}=\operatorname{rand}[-1,1]$ and limit=Dimension $\times$ Number of food sources $=D \times S N[1,26]$,
$-C=1.5[56]$,

It can be observed from Table 2 that AABCLS outperforms the considered algorithms most of the times in terms of accuracy, reliability and efficiency. Some other statistical tests like box-plots, the Mann-Whitney U rank sum test, acceleration rate (AR) [41], and performance indices [5] have also been done in order to analyze the algorithms output more intensively.

### 5.3 Statistical analysis

Algorithms ABC, GABC, BSFABC, OBLFABC, MABC and AABCLS are compared based on SR, AFE, and ME. First SR of all these algorithms is compared and if it is not possible to distinguish the performance of algorithms based on SR then comparison is made on the basis of AFE. ME is used for comparison if the comparison is not possible on the basis of SR and AFE both. From the results shown in Table 2, it is clear that AABCLS costs less on 27 test functions ( $f_{1}-f_{3}, f_{5}-f_{11}, f_{13}-f_{28}, f_{30}$ ) among all the considered algorithms. As these functions include unimodel, multimodel, separable, non separable, lower and

Fig. 4 Effect of parameter $p_{r}$ on success rate
higher dimensional functions, it can be stated that AAB CLS balances the exploration and exploitation capabilities efficiently. ABC, GABC, BSFABC and OBLFABC outperforms AABCLS over test function $f_{4}$, in which the global minimum is inside a long, narrow, parabolic shaped flat valley. The cost of OBLFABC is lower for four test functions $\left(f_{4}, f_{12}\right.$ and $\left.f_{29}\right)$ than the AABCLS, ABC, BSFABC and MABC which are multimodel functions. When AABCLS is compared with each of the considered algorithms individually, it is better than ABC, BSFABC and GABC over 29 test functions and it is better than MABC over all test functions of mixed characteristics. It means that when the results of all functions are evaluated together, the AABCLS algorithm is the cost effective algorithm for most of the functions. Now if AABCLS algorithm is compared based on mean error only then one can see from Table 2 that AABCLS is achieving less error on 21 out of 30 functions than all the other considered algorithms. ABC and BSFABC are good on 9 functions, OBLFABC is good on 7 functions and GABC is good on 5 functions while MABC is better on single function $f_{15}$ than the proposed AABCLS algorithm with respect to mean error.

Since boxplot [55] can efficiently represent the empirical distribution of results, the boxplots for AFE and ME for all algorithms AABCLS, ABC, GABC, BSFABC, OBLFABC and MABC have been represented in Fig. 5. Figure 5a shows that AABCLS is cost effective in terms of function evaluations as interquartile range and median of AFE are very low for AABCLS. Boxplot Fig. 5b shows that AABCLS and GABC are competitive in terms of ME as interquartile range for both the algorithms are very low and less than the other considered algorithms. Though, it is clear from box plots that AABCLS is cost effective than $\mathrm{ABC}, \mathrm{BSFABC}$, GABC, OBLFABC and MABC i.e., AABCLS's result differs from the other, now to check, whether there exists any significant difference between algorithm's output or this difference is due to some randomness, another statistical test is required. It can be observed from boxplots of Fig. 5 that

average number of function evaluations used by the considered algorithms and mean error achieved by the algorithms to solve the different problems are not normally distributed, so a non-parametric statistical test is required to compare the performance of the algorithms. The Mann-Whitney U rank sum [29], a non-parametric test, is well established test for comparison among non-Gaussian data. In this paper, this test is performed on average number of function evaluations and ME at $5 \%$ level of significance ( $\alpha=0.05$ )
between AABCLS-ABC, AABCLS-BSFABC, AABCLSGABC, AABCLS-OBLFABC and AABCLS-MABC.

Tables 3 and 4 show the results of the Mann-Whitney U rank sum test for the average number of function evaluations and ME of 100 simulations. First the significant difference is observed by Mann-Whitney U rank sum test i.e., whether the two data sets are significantly different or not. If significant difference is not seen (i.e., the null hypothesis is accepted) then sign ' $=$ ' appears and when significant difference is observed i.e., the null hypothesis is rejected then compare the AFE. The signs ' + ' and ' - ' are used for the case where AABCLS takes less or more average number of function evaluations than the other algorithms, respectively. Similarly, for mean error, if significant difference is observed then compare the ME and the signs ' + ' and ' - ' are used for the case where AABCLS achieves less or more mean error. Therefore in Tables 3 and 4, ' + ' shows that AABCLS is significantly better and ' - ' shows that AABCLS is significantly worse. As Tables 3 and 4 include 138 ' + ' signs for AFE case and 107 ' + ' signs for ME case out of 150 comparisons. Therefore, it can be concluded that the results of AABCLS is significantly cost effective than $\mathrm{ABC}, \mathrm{BSFABC}, \mathrm{GABC}$, OBLFABC and MABC over considered test problems.

Further, the convergence speeds of the considered algorithms are compared by measuring the AFEs. A smaller AFEs means higher convergence speed. In order to minimize the effect of the stochastic nature of the algorithms, the reported function evaluations for each test problem is averaged over 100 runs. In order to compare convergence speeds, the acceleration rate (AR) is used which is defined as follows, based on the AFEs for the two algorithms ALGO and AABCLS:
$A R=\frac{A F E_{A L G O}}{A F E_{A A B C L S}}$,
where, $\mathrm{ALGO} \in\{\mathrm{ABC}, \mathrm{BSFABC}, \mathrm{GABC}, \mathrm{OBLFABC}$ and MABC $\}$ and $A R>1$ means AABCLS is faster. In order to investigate the $A R$ of the proposed algorithm as compare to the considered algorithms, results of Table 2 are analyzed and the value of $A R$ is calculated using Eq. (9). Table 5 shows a comparison between AABCLS-ABC, AABCLS-BSFABC, AABCLS-GABC, AABCLS-OBLFABC, and AABCLSMABC in terms of $A R$. It is clear from the Table 5 that convergence speed of AABCLS is better than considered algorithms for most of the functions.

Further, to compare the considered algorithms by giving weighted importance to SR , AFE and ME, performance indices (PIs) are calculated [5]. The values of PI for the AABCLS, ABC, BSFABC, GABC, OBLFABC and MABC are calculated using following Equations:
$P I=\frac{1}{N_{p}} \sum_{i=1}^{N_{p}}\left(k_{1} \alpha_{1}^{i}+k_{2} \alpha_{2}^{i}+k_{3} \alpha_{3}^{i}\right)$

$T P$ test problem, ' + ' indicates AABCLS is significantly better, ' - ' indicates AABCLS is worse and ' $=$ ' indicates that there is no significant difference)

Where $\alpha_{1}^{i}=\frac{S r^{i}}{T r^{i}} ; \alpha_{2}^{i}=\left\{\begin{array}{ll}\frac{M f^{i}}{A f^{i}}, & \text { if } S r^{i}>0 . \\ 0, & \text { if } S r^{i}=0 .\end{array} ;\right.$ and $\alpha_{3}^{i}=$ $\frac{M o^{i}}{A o^{i}} i=1,2, \ldots, N_{p}$
$-S r^{i}=$ Successful simulations/runs of $i^{t h}$ problem.

- $T r^{i}=$ Total simulations of $i^{t h}$ problem.
$-M f^{i}=$ Minimum of AFE used for obtaining the required solution of $i^{\text {th }}$ problem.
$-A f^{i}=$ AFE used for obtaining the required solution of $i^{\text {th }}$ problem.
$-M o^{i}=$ Minimum of ME obtained for the $i^{t h}$ problem.
$-A o^{i}=$ ME obtained by an algorithm for the $i^{t h}$ problem.
$-N_{p}=$ Total number of optimization problems evaluated.

The weights assigned to $\mathrm{SR}, \mathrm{AFE}$ and ME are represented by $k_{1}, k_{2}$ and $k_{3}$ respectively, where $k_{1}+k_{2}+k_{3}=1$ and $0 \leq k_{1}, k_{2}, k_{3} \leq 1$. To calculate the $P I \mathrm{~s}$, equal weights are assigned to two variables while weight of the remaining variable vary from 0 to 1 as given in [10]. Following are the resultant cases:

1. $k_{1}=W, k_{2}=k_{3}=\frac{1-W}{2}, 0 \leq W \leq 1$;
2. $k_{2}=W, k_{1}=k_{3}=\frac{1-W}{2}, 0 \leq W \leq 1$;
3. $k_{3}=W, k_{1}=k_{2}=\frac{1-W}{2}, 0 \leq W \leq 1$

The graphs corresponding to each of the cases (1), (2) and (3) for the considered algorithms are shown in Fig. 6a-c respectively. In these figures the weights $k_{1}, k_{2}$ and $k_{3}$ are

represented by horizontal axis while the $P I$ is represented by the vertical axis.

In case (1), AFE and ME are given equal weights. PIs of the considered algorithms are superimposed in Fig. 6a for comparison of the performance. It is observed that PI of AABCLS is higher than the considered algorithms. In case (2), equal weights are assigned to SR and ME and in case (3), equal weights are assigned to SR and AFE . It is clear from Fig. 6 b and c that the algorithms perform same as in case (1).

## 6 Conclusion

ABC is a simple algorithm having very less parameters with drawbacks like premature convergence and poor in exploitation. In order to develop an ABC algorithm with better exploitation and exploration capabilities, this article proposed a modified position update equation for ABC in which individuals update their respective positions in guidance of global best individual on the basis of fitness. Fur-

Fig. 6 Performance index for test problems; a for case (1), b for case (2) and $\mathbf{c}$ for case (3)
ther, a self adaptive local search strategy which is based on greedy logarithmic decreasing step size, is proposed and incorporated with ABC to enhance the exploitation capability. The proposed algorithm has been extensively compared with other recent variants of ABC namely, BSFABC, GABC, OBLFABC, and MABC. Based on various computational and statistical analyses, it is found that AABCLS achieves better success rate in less number of function evaluations with less ME on most of the problems considered. Through the extensive experiments, it can be stated that the proposed algorithm is a competitive algorithm to solve the continuous optimization problems. In future, work will be extended to solve constrained and real world problems.
